

**Key Points:**

- Mercury's disappearing dayside magnetosphere event under extreme solar wind conditions is studied by using 3-D global hybrid simulations
- Most of the dayside magnetosphere, even the dayside bow shock, disappears shortly after the interaction between the extreme solar wind and the planetary magnetic field
- Ion precipitation on the planetary surface and the time evolution of magnetopause standoff distance under different solar wind conditions are also studied

**Abstract** An important discovery of MESSENGER is the occurrence of dayside disappearing magnetosphere (DDM) events that occur when the solar wind dynamic pressure is extremely high and the interplanetary magnetic field (IMF) is both intense and southward. In this study, we investigate the DDM events at Mercury under extreme solar wind conditions using a three-dimensional (3-D) global hybrid simulation model. Our results show that when the solar wind dynamic pressure is 107 nPa and the magnitude of the purely southward IMF is 50 nT, most of the dayside magnetosphere disappears within 10 s after the interaction between the solar wind and the planetary magnetic field starts. During the DDM event, the ion flux is significantly enhanced at most of the planetary dayside surface and reaches its maximum value of about  $10^{10} \text{ cm}^{-2} \text{ s}^{-1}$  at the low-latitude surface, which is much larger than that under normal solar wind conditions. During the DDM events, the dayside bow shock mostly disappears for about 9 s and then reappears. Moreover, the time evolution of magnetopause standoff distance under different solar wind conditions is also studied. When the solar wind dynamic pressure exceeds 25 nPa and the IMF is purely southward, a part of the dayside magnetosphere disappears. Under the same IMF, the higher the solar wind dynamic pressure, the faster the magnetopause standoff distance reaches the planetary surface. When the solar wind conditions are normal (with a dynamic pressure of 8 nPa) or the IMF is purely northward, the dayside magnetosphere does not disappear. The results provide a clear physical image of DDM events from a 3-D perspective.

**Plain Language Summary** Mercury has a significant, and apparently global, magnetic field. The planetary magnetic interacts with the solar wind originating from the Sun, creating a magnetosphere. However, it has been observed that the dayside part of the planetary magnetosphere can disappear, which is referred to as dayside disappearing magnetosphere (DDM) events. These events normally occur when the solar wind dynamic pressure is extremely high and the magnetic field in the solar wind is both intense and southward. In this study, we use computer simulations to investigate the DDM events at Mercury under extreme solar wind conditions. Our results show that most of the dayside magnetosphere disappears after the interaction between the extreme solar wind and the planetary magnetic field, leading to a significant enhancement in the precipitation of ion flux on the planetary surface. Moreover, the temporal evolution of the dayside magnetosphere's size under different solar wind conditions was also studied. Under the same solar wind magnetic field, the higher the solar wind dynamic pressure, the smaller the magnetosphere. The results provide a clear physical image of DDM events from a 3-D perspective.

### 1. Introduction

A major scientific discovery during the Mariner 10's flybys of Mercury was that the planet has a weak intrinsic magnetic field (less than 1% of Earth's magnetic field, Ness et al., 1974). The magnetic field measurements from the MERcury Surface, Space ENvironment, GEochemistry, and Ranging mission (MESSENGER) spacecraft, launched in 2004, revealed that Mercury's dipolar magnetic moment is closely aligned with its rotation axis and has a northward offset of about 0.2 times the radius of Mercury ( $R_M$ , which is 2,440 km) (Alexeev et al., 2010; Anderson et al., 2011). This magnetic offset leads to notable north-south asymmetries in both the polar magnetic field and the size of the polar caps (Korth et al., 2018). The weak intrinsic magnetic field of Mercury interacts with the solar wind, forming a miniature magnetosphere with a typical magnetopause standoff distance of about

$1.5R_M$  from the center of Mercury's internal magnetic dipole (Winslow et al., 2013). This miniature magnetosphere effectively shields the planet from the direct impact of solar wind particles. Many physical phenomena during the solar wind-magnetosphere interaction, such as flux transfer event (FTE) showers at the magnetopause (Lu et al., 2022; Slavin et al., 2012; Sun et al., 2020), ultra-low frequency waves in the foreshock (Le et al., 2013; Romanelli & DiBraccio, 2021; Romanelli et al., 2020), ring current in the inner magnetosphere (Shi et al., 2022; Zhao et al., 2022), Kelvin-Helmholtz waves in the magnetospheric flanks (Gershman et al., 2015; Liljeblad et al., 2014; Slavin et al., 2008; Sundberg et al., 2011), very fast reconnection, more than three times faster than that observed at Earth (DiBraccio et al., 2013; Slavin et al., 2009), and dawn-dusk asymmetries in the magnetotail reconnection (Liu et al., 2019; Smith et al., 2017; Sun et al., 2016), have been widely studied.

Mercury possesses a large-size, electrically conducting iron core with a radius of approximately  $0.8R_M$  (e.g., Smith et al., 2012), which distinguishes it from other planets in the solar system. The electromagnetic coupling between Mercury's conducting core and its space environment has significant effects on the solar wind-magnetosphere interaction (e.g., Hood & Schubert, 1979; Suess & Goldstein, 1979). Under varying solar wind conditions, the position of Mercury's magnetopause changes relative to the planetary surface. The magnetopause motion and the corresponding changes of the current system lead to magnetic field perturbations within Mercury's interior and near its surface, causing induced currents in the conducting core (Heyner et al., 2016; Slavin et al., 2014). The induced currents further produce magnetic fields that can constitute a significant fraction of Mercury's weak intrinsic field (Glassmeier et al., 2007). Hence, the magnetic field induced by the currents in the planetary core enhances the dipolar magnetic field of Mercury and provides a shield for the planet, limiting the direct impact of the solar wind particles on the planetary surface (Dong et al., 2019; Jia et al., 2015, 2019).

During major coronal mass ejection impacts, the dayside magnetosphere of Mercury can be highly compressed (Jia et al., 2019; Slavin et al., 2014) and even “disappear” (Slavin et al., 2019; Winslow et al., 2020; Zhong et al., 2015). These intervals are termed “disappearing dayside magnetosphere” (DDM) events. Slavin et al. (2019) examined four low-altitude MESSENGER passes over the dayside hemisphere of Mercury for which no dayside magnetosphere, only magnetosheath was observed. Such events, or ones similar to them, have been noted previously by Zhong et al. (2015) and Winslow et al. (2020) but not analyzed in detail. These magnetospheric responses to the upper ranges solar wind dynamic pressures and southward interplanetary magnetic field (IMF) intensity in the MESSENGER observations at Mercury have been divided into two categories: highly compressed magnetosphere (HCM) events and DDM events. HCM events are characterized by magnetospheric magnetic field intensities just inside of the subsolar magnetopause of  $>300$  nT and correspond to solar wind dynamic pressures in the MESSENGER data of approximately 40–90 nPa (Jia et al., 2019). The magnetopause crossings during the HCM events were analyzed in the MESSENGER data and were found to have significant normal magnetic fields to the magnetopause despite 7 of the 8 events having magnetic shear angles across the magnetopause less than  $90^\circ$  (Jia et al., 2019). The DDM events, in contrast, are associated with more severe upstream dynamic pressures of about 140–290 nPa (Slavin et al., 2019), respectively. The MESSENGER DDM magnetopause crossings appeared to present only at very high latitudes, about  $66\text{--}80^\circ$ , just sunward of the day-night terminator plane. The magnetic fields in the dayside DDM magnetosheath were very intense and strongly southward,  $B_z$  about  $-100$  to  $-400$  nT (Slavin et al., 2019).

These observations indicate that the extreme solar wind compression and reconnection-driven erosion of Mercury's dayside magnetosphere lead to the DDM events. Due to the limited observations from the MESSENGER spacecraft, it is difficult to study the DDM events in detail, such as the three-dimensional (3-D) shape and time evolution of Mercury's magnetosphere and the ion flux precipitating on the planetary surface. Although various numerical models, including global magnetohydrodynamic (MHD) (Jia et al., 2015, 2019; Kabin, 2000; Kabin et al., 2008; Kidder et al., 2008; Varela et al., 2015) and Hall MHD (Li et al., 2023), hybrid models (Exner et al., 2018, 2020; Fatemi et al., 2020; Kallio & Janhunen, 2003; Müller et al., 2012; Trávníček et al., 2007, 2010; Wang et al., 2010), and particle-in-cell model (Lapenta et al., 2022), have been performed to study the space environment of Mercury, DDM events still have not been studied using simulations.

Additionally, Potter and Morgan (1985) discovered abundant Na vapor in the planetary exosphere, with an estimated total column abundance of  $8.1 \times 10^{11}$  atoms  $\text{cm}^{-2}$ . They proposed that the source of Na could be ion sputtering, where ions originate from the solar wind or Mercury's magnetosphere. However, McGrath et al. (1986) estimated that the average Na column abundance resulting from ion sputtering under normal solar wind conditions is more than three orders of magnitude lower than the observed value. Hence, it is worth investigating whether ion sputtering can account for the source of Na during the DDM event.

In this study, we investigate the DDM events at Mercury under extreme solar wind conditions using a 3-D global hybrid simulation model. The simulation results demonstrate that most of the dayside magnetosphere disappears within 10 seconds after the interaction between the planetary magnetic field and the solar wind with extreme dynamic pressure and intense southward IMF. Due to the disappearance of the dayside magnetosphere, the ion flux at Mercury's surface is significantly enhanced compared to that under normal solar wind conditions. Due to this enhanced solar wind absorption as it impacts Mercury's surface, most of the dayside bow shock disappears until the initiation of the magnetotail reconnection. The dayside bow shock reappears once the magnetotail reconnection returns magnetic flux to the dayside magnetosphere. Moreover, we also examine the time evolution of magnetopause standoff distance under different solar wind conditions. The results provide a clear physical image of DDM events from a 3-D perspective and demonstrate how the Dungey cycle (Dungey, 1961) of magnetic flux circulation operates under extreme solar wind and IMF conditions in this small magnetosphere.

## 2. Simulation Model

A 3-D global hybrid code, named general curvilinear particle-in-cell (gcPIC) hybrid for Mercury, is used to simulate the DDM events at Mercury. The gcPIC is a software package that can implement kinetic simulations, including full particle simulation and hybrid simulation, in a general curvilinear coordinate system. The software package has previously been successfully used to study the excitation of chorus waves in a dipole magnetic field (Lu et al., 2019) and the FTE showers at Mercury (Lu et al., 2022). Hybrid simulation has been shown to be suitable for studying the planetary magnetosphere on a global scale (Guo et al., 2021, 2022). In the hybrid code, ions are treated as particles, and electrons are treated as a massless fluid, assuming quasi-charge neutrality. The hybrid simulation model adopts the Mercury Solar Orbital (MSO) coordinate system, where the  $+x$  axis points to the Sun (i.e., the solar wind flows along the  $-x$  axis), the  $+y$  axis is opposite to the orbital motion of Mercury around the Sun and points toward dusk, and the  $+z$  axis points to the geographical north. The simulation domain size is  $-7R_M \leq x \leq 3R_M$ ,  $-3R_M \leq y \leq 3R_M$ , and  $-5R_M \leq z \leq 5R_M$ . Cartesian coordinates are used in the calculations. In this hybrid simulation model, Mercury is assumed to be a spherical object without an exosphere, and particles are absorbed at the planetary surface. Conducting boundary conditions for electromagnetic fields are applied at the inner boundary ( $r = 0.55R_M$ ).

In the space environment ( $r > 1R_M$ ), the electric field  $\mathbf{E}$  is obtained from the massless electron momentum equation:

$$\mathbf{E} = -\mathbf{V}_e \times \mathbf{B} - (1/N)\nabla p_e - \nu(\mathbf{V}_e - \mathbf{V}_i), \quad (1)$$

where  $\mathbf{B}$  is the magnetic field,  $N$  is the total ion number density,  $\mathbf{V}_i$  is the total ion bulk flow velocity,  $\mathbf{V}_e$  is the electron bulk flow velocity obtained from Ampere's law,  $\nabla p_e$  is the electron pressure gradient, and  $\nu$  is an ad hoc current-dependent collision frequency used to simulate the anomalous resistivity. The electron fluid is assumed to be isothermal, with a constant temperature  $T_e$ , and  $\nabla p_e = T_e \nabla N$ . The magnetic field is advanced in time by Faraday's law

$$\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times \mathbf{E}. \quad (2)$$

Inside the planet ( $0.55R_M < r \leq 1R_M$ ), where the plasma convection is neglected, the bulk flow velocity of ions and the  $(1/N)\nabla p_e$  are set to zero. Therefore, the magnetic field equation inside the planet becomes a pure diffusion equation:

$$\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times \mathbf{E} = -\nabla \times \left( \frac{\eta}{\mu_0} \nabla \times \mathbf{B} \right), \quad (3)$$

where  $\eta$  is the resistivity. According to the previous studies (Dong et al., 2019; Jia et al., 2015), the resistivity  $\eta$  is  $10^{-5} \Omega \text{ m}$  within the conducting core ( $0.55R_M < r \leq 0.8R_M$ ) and  $10^7 \Omega \text{ m}$  in the insulated mantle ( $0.8R_M < r \leq 1R_M$ ).

Mercury's dipole moment is set to  $190 \text{ nT } R_M^3$  along the  $z$ -direction, with a  $0.2R_M$  offset northward from the center of the planet (Anderson et al., 2011). Initially, the dipole magnetic field is confined to  $x \leq 2R_M$  by adding an image dipole. A uniform solar wind carrying a steady IMF is filled in the region  $x > 2R_M$  with the front side boundary at  $x = 3R_M$ . Outflow boundary conditions are used at  $x = -7R_M$ ,  $y = \pm 3R_M$  and  $z = \pm 4R_M$ . A nonuniform

Note.  $B_{sw}$  is the IMF;  $N_{i0}$  is the solar wind number density;  $V_{sw}$  is the solar wind speed;  $P_{dyn0}$  is the dynamic pressure in the solar wind;  $M_A$  is the Mach number;  $\beta$  is the ratio of the plasma thermal pressure to the magnetic pressure in the solar wind;  $d_i$  is the solar wind ion inertial length, and  $N_x \times N_y \times N_z$  is the number of grids. Note that Case 6 has time-varying solar wind conditions. These solar wind parameters are from Jia et al. (2019) and are estimated by the observation of MESSENGER.

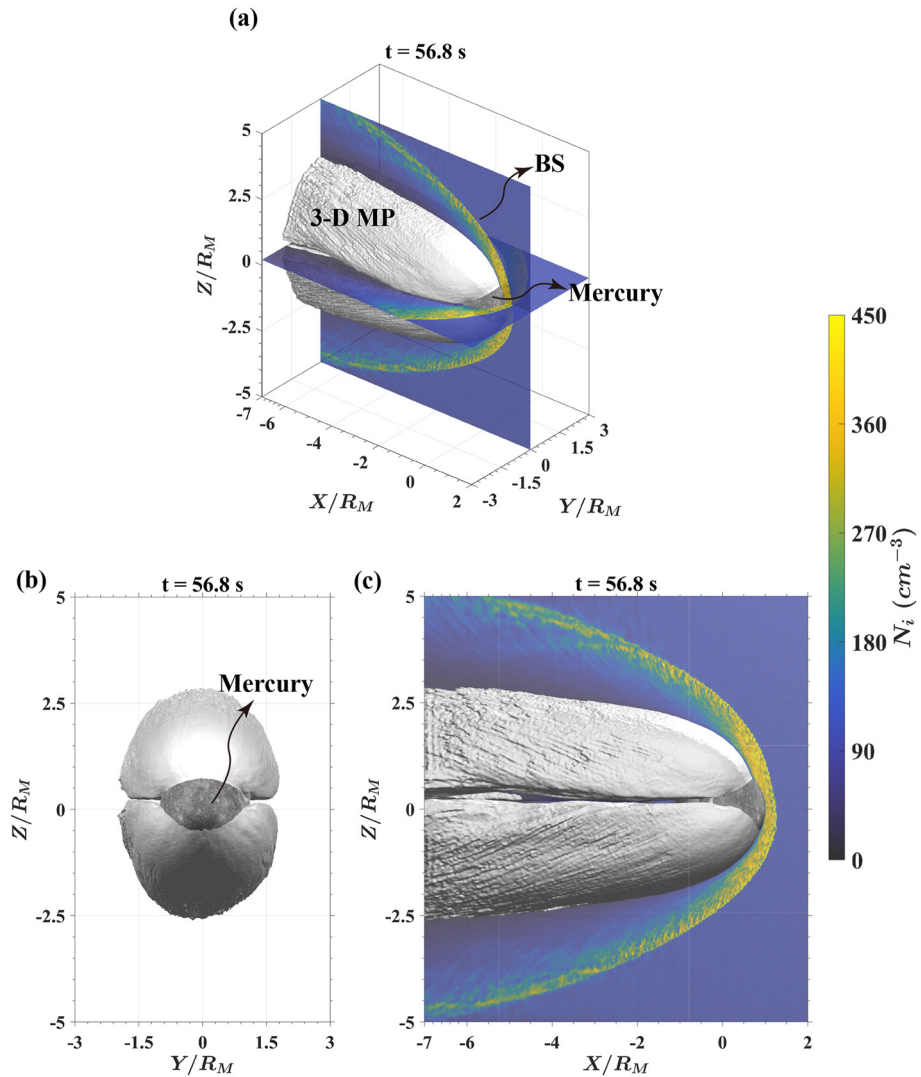

grid cell system is employed, with a grid size of  $(\Delta x, \Delta y, \Delta z) \approx (1d_i, 1.5d_i, 1d_i)$  ( $d_i$  is the solar wind ion inertial length) in the near-Mercury regions with  $-2R_M < x < 2R_M$ ,  $-2R_M < y < 2R_M$ , and  $-2R_M < z < 2R_M$  and a lower resolution in the lobes. The solar wind conditions, as well as the number of grids and particles in each case, are shown in Table 1. In Case 1, the solar wind conditions are extreme, while in Case 4, the solar wind conditions are normal. Note that in Case 6, the dynamic pressure in the solar wind changes from 8 to 25 nPa about 100 s after the simulation begins; in Case 7, the solar wind dynamic pressure increases from 8 to 107 nPa about 23 s after the simulation begins. Other plasma parameters are also time varying in this case. The time step  $\Delta t$  is chosen as  $0.008\text{--}0.02 \Omega_i^{-1}$ , where  $\Omega_i$  is the ion gyrofrequency based on the IMF intensity.

### 3. Simulation Results

#### 3.1. Extreme Solar Wind Condition (Case 1)

In Case 1, the dynamic pressure of the solar wind is chosen to be 107 nPa, and the magnitude of purely southward IMF is 50 nT, representing an extreme solar wind condition. The solar wind parameters were chosen based on their proximity to the observations in Slavin et al. (2019), their ability to reduce the computational resources required (higher dynamic pressure necessitates higher grid resolution), and their facilitation of intercomparisons among the individual simulation cases. The magnetotail is well formed at about  $t = 45$  s, and the standoff distance of the dayside bow shock is steady. Figure 1 shows the 3-D views of Mercury's magnetopause at  $t = 56.8$  s in Case 1. The white surface represents the 3-D magnetopause, while the region with enhanced plasma density is the magnetosheath. The bow shock is located between the solar wind and the magnetosheath. Due to the northward offset of the internal dipole, both the magnetopause and the magnetotail are shifted northward (refer to Figures 1b and 1c). In Figure 1, most of the dayside magnetosphere disappears, allowing particles from the magnetosheath to directly impact the planetary surface. About 26% of the dayside surface of Mercury is in contact with the magnetosheath. The standoff distance of the dayside bow shock (at  $z = 0.2R_M$ ) is merely about  $1.3R_M$ , which is very close to the planetary surface. It also compares favorably with the  $1.5R_M$  mean stand-off distance derived from fitting the location of the bow shock during the 4 DDM events in the Slavin et al. (2019) MESSENGER study.

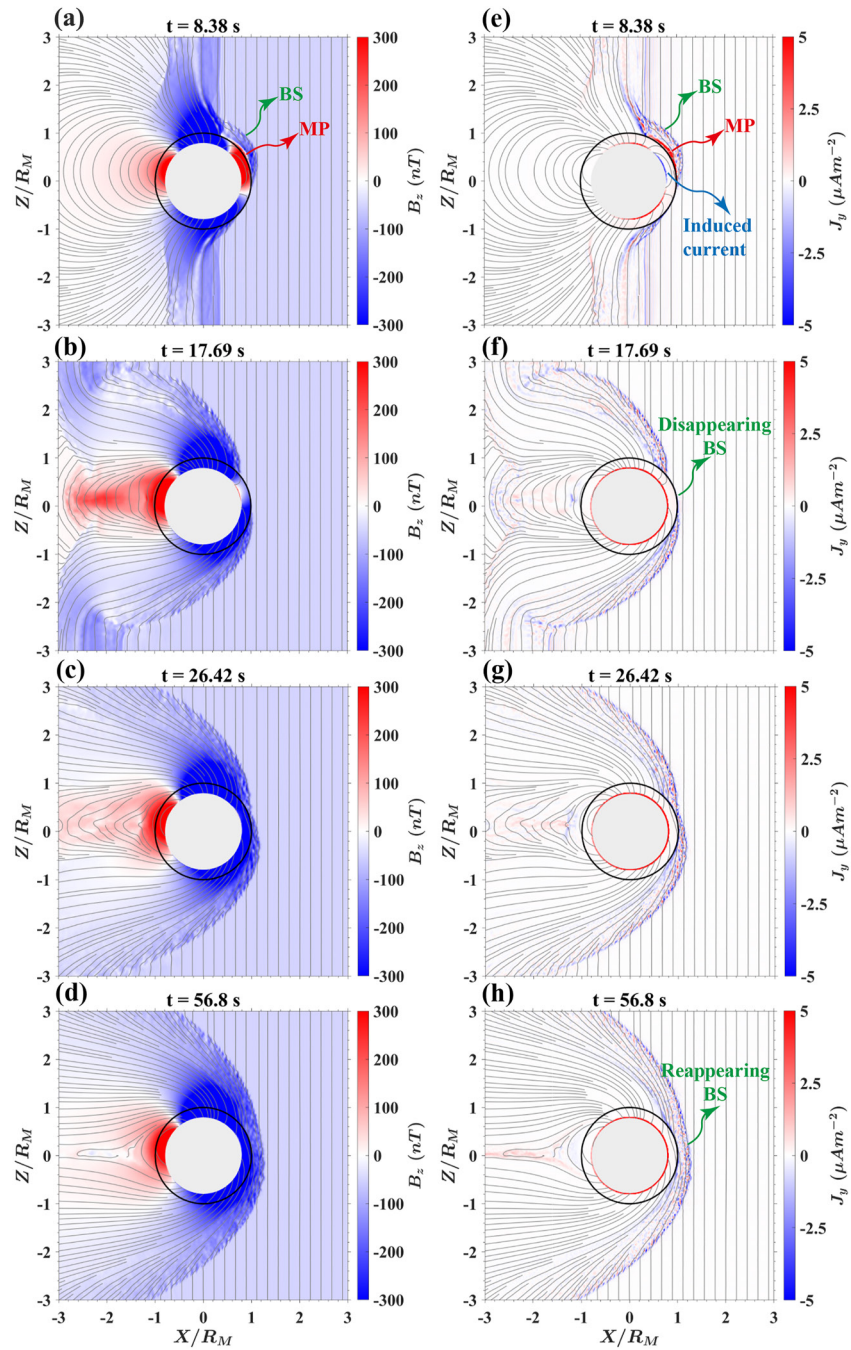

Figure 2 illustrates the evolution of the magnetosphere and bow shock in Case 1. Due to the strong dynamic pressure in the solar wind, the dayside magnetosphere becomes highly compressed at  $t = 8.38$  s (Figures 2a and 2e), resulting in the formation of intense Chapman-Ferraro currents at the magnetopause. The compression by the solar wind induces currents at the surface of the planetary core, leading to the formation of two current circuits that generate an induced magnetic field to prevent the compression. This result is consistent with previous simulation models for Mercury (Dong et al., 2019; Jia et al., 2015). At  $t = 17.69$  s (Figures 2b and 2f), most of the dayside magnetosphere disappears, and the induced current circuits at the surface of the planetary core also

**Figure 1.** 3-D views of Mercury's magnetopause at  $t = 56.8$  s obtained from Case 1. (a) The slices show the ion number density,  $N_i$ , in the noon-midnight meridian and equatorial planes. Mercury is indicated by a dark gray sphere. The 3-D magnetopause (3-D MP) is indicated by the white surface and is defined by the parameter  $\beta^* = (P_{th} + P_{dyn})/P_{mag}$ , where  $P_{th}$  is the plasma thermal pressure and  $P_{mag}$  is the magnetic pressure. The value range of  $\beta^*$  between 0.1 and 1.5, which was demonstrated by Brenner et al. (2021), is used to define the magnetopause. In this study,  $\beta^* = 0.1$  is utilized to define the 3-D magnetopause, consistent with Ala-Lahti et al. (2022). (b) Views of the magnetopause from the direction of sunlight. (c) Views of the magnetopause from dawn to dusk.

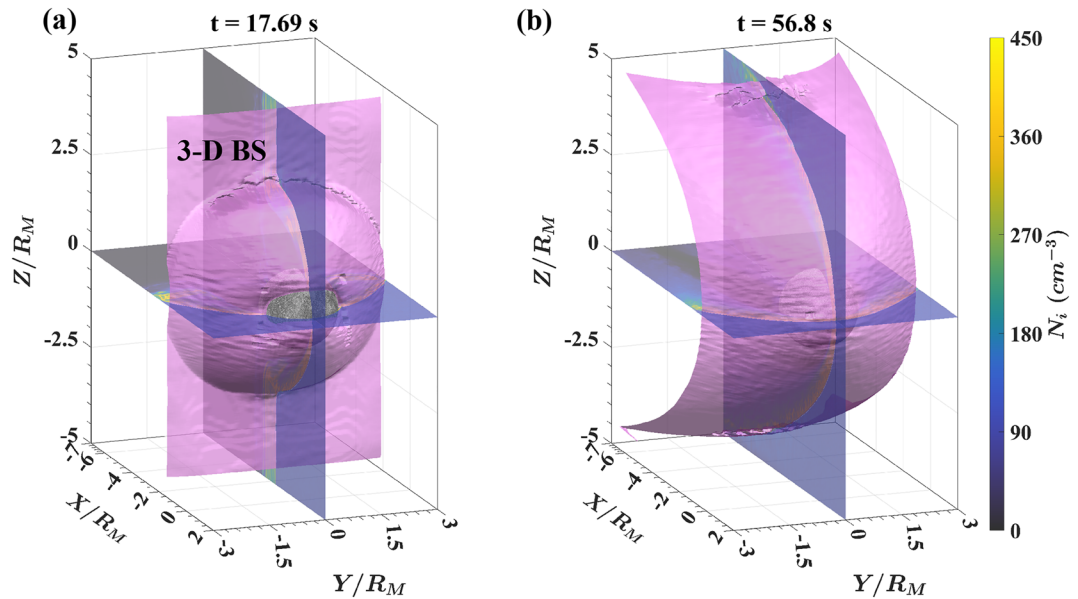

disappear. Additionally, most of the dayside bow shock also disappears at this time, indicating that the solar wind particles can directly impact the surface of Mercury without being decelerated by the bow shock. At  $t = 26.42$  s (Figures 2c and 2g), the magnetotail is formed, triggering magnetotail reconnection and resulting in the return of the magnetic flux from the magnetotail to the dayside magnetosphere. Therefore, the dayside bow shock is reappearing at this time. Finally, at  $t = 56.8$  s (Figures 2d and 2h), the dayside bow shock reappears completely, while the dayside magnetosphere remains disappeared. The dayside bow shock disappears for about 9 s. The occurrence time of disappearing dayside magnetosphere and bow shock is much shorter than the Dungey cycle time scale of Mercury,  $\sim 2$  min (Slavin, Anderson, et al., 2010).

To better illustrate the phenomenon of the disappearing dayside bow shock, Figure 3 plots the 3-D views of the bow shock (magenta surface) at two specific times,  $t = 17.69$  and  $56.8$  s, in Case 1. In Figure 3a, most of the dayside bow shock disappears at  $t = 17.69$  s, causing about 20% of the dayside surface of Mercury to be impacted directly by the solar wind. However, at  $t = 56.8$  s, once the magnetotail is fully formed and the magnetic flux returns to the dayside magnetosphere, the dayside bow shock reappears completely (Figure 3b).

**Figure 2.** The evolution of the magnetopause and the bow shock in the noon-midnight meridian plane obtained from Case 1. (a–d) The magnetic field lines and the  $z$  component of magnetic field,  $B_z$ , at  $t = 8.38$  s, 17.69 s, 26.42 s, and 56.8 s. (e–h) The magnetic field lines and the  $y$  component of current density  $J_y$  at the same time points. The green arrow denotes the location of the bow shock, while the red arrow indicates the position of the magnetopause. The blue arrow indicates the induced currents at the core surface of Mercury. The surface of Mercury is represented by a black circle, and the core of Mercury is represented by a gray circular region.

Figure 4 illustrates the ion flux at the planetary surface at  $t = 56.8$  s in Case 1. Due to the disappearance of the dayside magnetosphere, the ion flux is significantly enhanced at most of the dayside surface (Figure 4a) and reaches its maximum value of about  $10^{10} \text{ cm}^{-2} \text{ s}^{-1}$  at the low-latitude surface. In the nightside hemisphere (Figure 4b), the ion flux at the surface is mainly provided by the outflow of the magnetotail reconnection. The highest peak of the ion flux, about  $10^9 \text{ cm}^{-2} \text{ s}^{-1}$ , occurs at the high latitudes of both the northern and southern

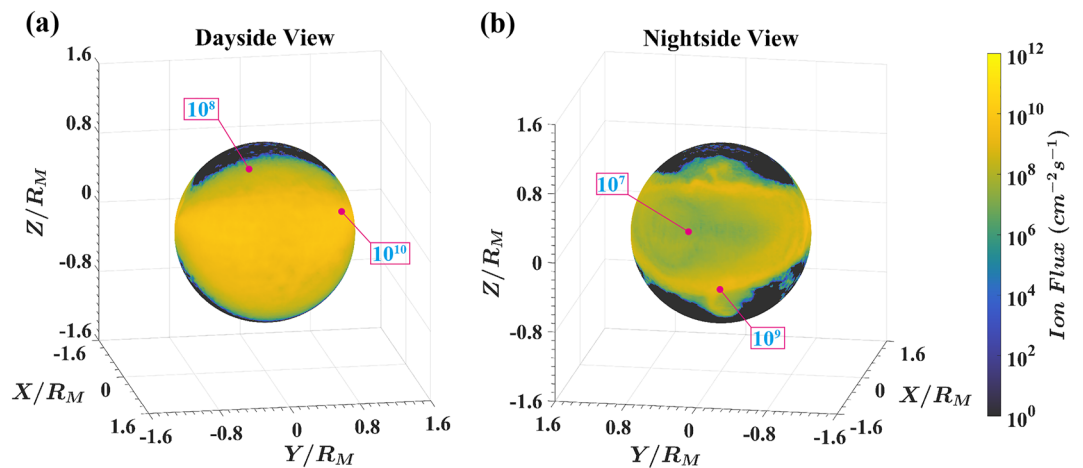

**Figure 3.** 3-D views of the bow shock at  $t = 17.69$  and  $56.8$  s obtained from Case 1. The slices show the ion number density,  $N_i$ , in the noon-midnight meridian and equatorial planes at (a)  $t = 17.69$  and (b)  $56.8$  s, respectively. The 3-D bow shock is indicated by the magenta surface in each panel and is identified by locating the highest gradient of the total velocity.

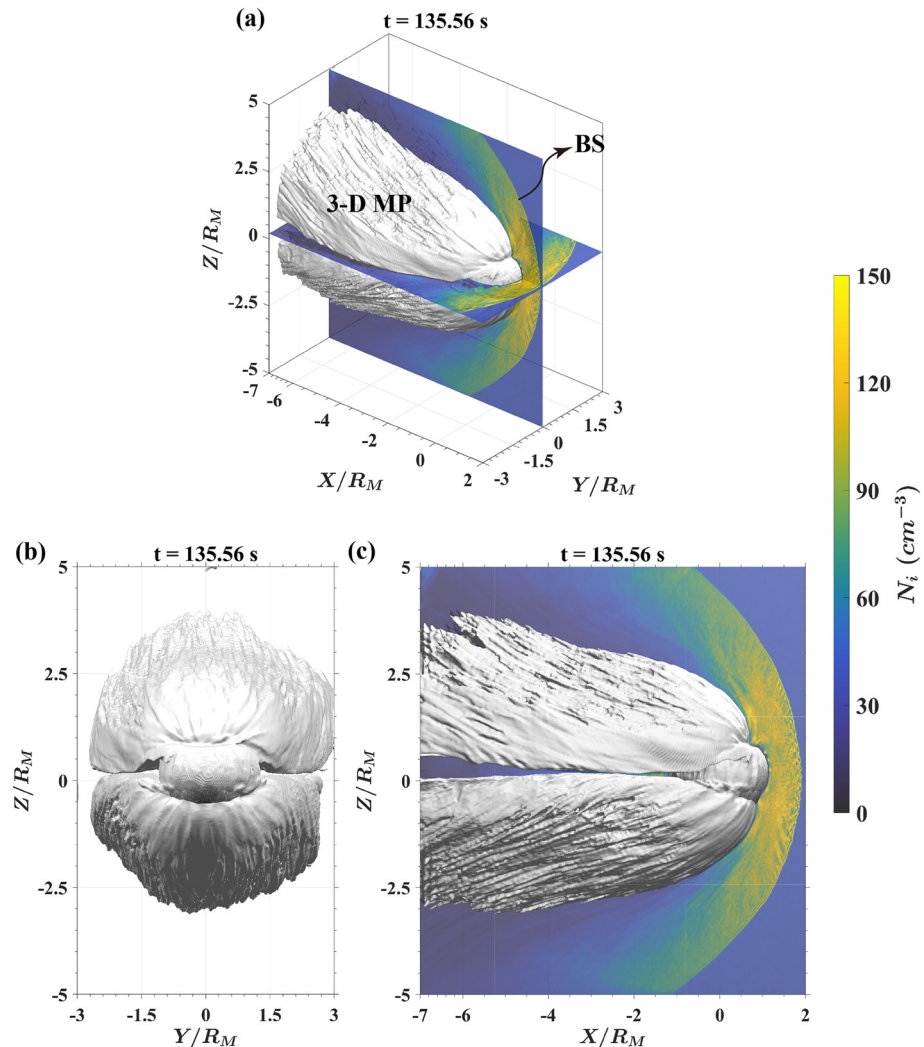

hemispheres, while the ion flux at low latitudes is merely about  $10^7 \text{ cm}^{-2} \text{ s}^{-1}$ . This is because at high latitudes there are open magnetic field lines that map to the region just inside the separatrix layers formed by reconnection, allowing particles to precipitate onto the planetary surface. However, at the low latitudes, there are close field lines that provide a shield for the planetary surface against direct plasma impact. The total ion precipitation rate in the dayside hemisphere is  $4.3 \times 10^{26} \text{ s}^{-1}$ , while in the nightside hemisphere, it is  $4.1 \times 10^{25} \text{ s}^{-1}$ .

### 3.2. Normal Solar Wind Condition (Case 4)

In Case 4, as a comparison case, the dynamic pressure and the magnitude of IMF (purely southward) in the solar wind are chosen to be  $8 \text{ nPa}$  and  $34 \text{ nT}$ , respectively, to represent normal solar wind conditions. The magnetotail is well formed at about  $t = 105 \text{ s}$ . Figure 5 shows the 3-D views of Mercury's magnetopause at  $t = 135.56 \text{ s}$  in Case 4, with the white surface representing the 3-D magnetopause. The magnetosheath is the region with enhanced ion density. In this case, the dayside magnetosphere does not disappear. The standoff distances of the dayside magnetopause and bow shock (at  $z = 0.2R_M$ ) are about  $1.15R_M$  and  $1.85R_M$ , respectively. The bow shock to the

**Figure 4.** 3-D views of ion flux at Mercury's surface at  $t = 56.8 \text{ s}$  obtained from Case 1. (a) View of dayside hemisphere. (b) View of nightside hemisphere.

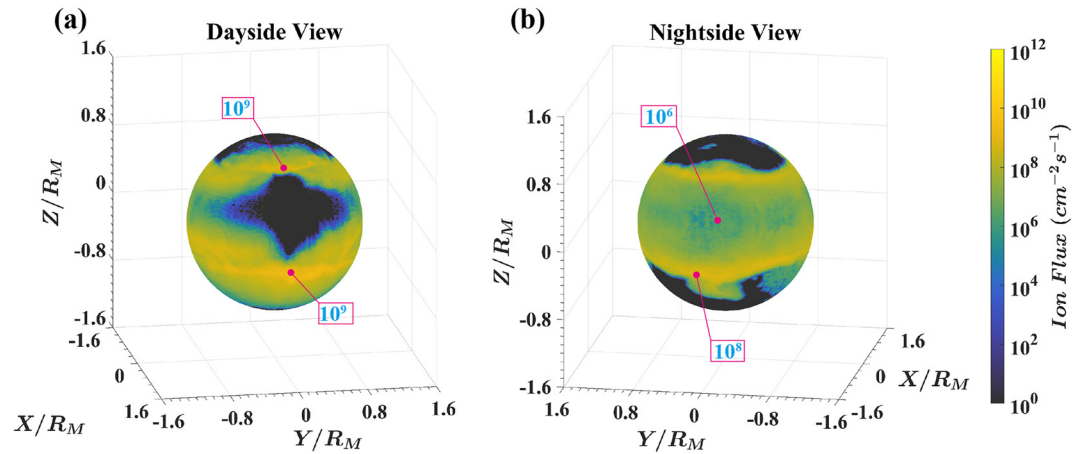

**Figure 5.** 3-D views of Mercury's magnetopause at  $t = 135.56$  s obtained from Case 4. The rest are in the same format as Figure 1.

magnetopause standoff distance ratio is approximately 1.6 for a Mach number of 3. However, at Earth, this ratio is only around 1.3 for a relatively high Mach number ranging from 8 to 10 (Spreiter et al., 1966).

Figure 6 plots the ion flux at the planetary surface at  $t = 135.56$  s under normal solar wind conditions (Case 4). In the dayside hemisphere (Figure 6a), there is a region characterized by low ion flux because the dayside magnetosphere blocks particles from the solar wind. However, in the cusp regions, the ion flux can reach up to about  $10^9 \text{ cm}^{-2} \text{ s}^{-1}$ , which is consistent with the observation by Raines et al. (2022). Due to the northward offset of the internal dipole, the southern cusp region is larger than the northern cusp region. In the nightside hemisphere, the peak of ion flux (about  $10^8 \text{ cm}^{-2} \text{ s}^{-1}$ ) is at the high latitudes of both the northern and southern hemispheres, while the ion flux at low latitudes is about  $10^6 \text{ cm}^{-2} \text{ s}^{-1}$ . The total ion precipitation rate in the dayside hemisphere is  $2.9 \times 10^{25} \text{ s}^{-1}$ , which is consistent with the observed values (Poh et al., 2016; Sun et al., 2022). In the nightside hemisphere, the total ion precipitation rate is  $1.3 \times 10^{25} \text{ s}^{-1}$ . It is noted that the total ion precipitation rate in the dayside hemisphere under normal solar wind conditions (Case 4) is more than an order of magnitude less than that under the extreme solar wind conditions shown in Case 1.

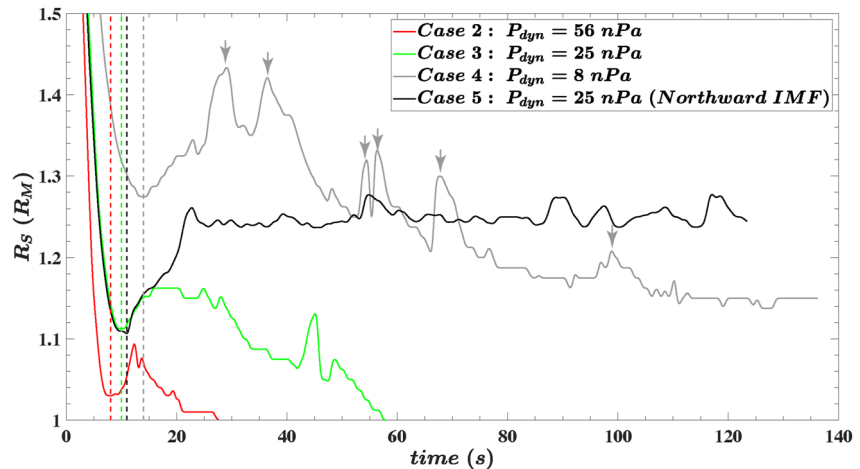

### 3.3. DDM Events Under Different Solar Wind Conditions

To determine how long it takes for DDM events to occur and the solar wind conditions under which DDM events occur, Figure 7 shows the temporal evolution of the magnetopause standoff distance in Cases 2–5. In Cases

**Figure 6.** 3-D views of ion flux at Mercury's surface at  $t = 56.8$  s obtained from Case 4. (a) View of dayside hemisphere. (b) View of nightside hemisphere.

2–4, only the dynamic pressure in the solar wind is changed (see Table 1), while the IMF is the same. In Case 2 (red line), with a dynamic pressure of 56 nPa in the solar wind, the magnetopause standoff distance reaches the minimum value of about  $1.03R_M$  at  $t = 8$  s (indicated by the red dashed vertical line). This represents the time taken for the conducting core to respond to changes in the magnetopause position. During the response time (8 s), the magnetic field perturbations generated by the motion of magnetopause are transported at the Alfvén speed toward the planetary surface, and the Alfvén wave then reflects at the core surface and is transported back to the magnetopause. Subsequently, the magnetopause standoff distance gradually increases due to the induced magnetic field produced by the currents at the core surface. The maximum value of the magnetopause standoff distance reaches up to  $1.09R_M$  at  $t = 12$  s. However, the dayside magnetopause is eroded by the magnetopause reconnection, causing the magnetopause standoff distance to reach  $1R_M$  at  $t = 27$  s. This implies that part of the dayside magnetosphere disappears. In Case 3 (green line), with a dynamic pressure of 25 nPa in the solar wind, the magnetopause standoff distance reaches its minimum value of about  $1.11R_M$  at  $t = 10$  s (indicated by the green dashed vertical line) when the induced currents at the core surface are well formed. Then, the magnetopause standoff distance gradually increases to  $1.16R_M$  at  $t = 16$  s and reaches  $1R_M$  at  $t = 58$  s, indicating that part of the dayside magnetosphere has also disappeared. In Case 4 (gray line), as shown in Section 3.2, the dynamic pressure in the solar wind is 8 nPa, which represents a normal solar wind condition (Sun et al., 2021). The minimum value of the magnetopause distance of about  $1.27R_M$  occurs at  $t = 14$  s (indicated by the gray dashed vertical

**Figure 7.** Temporal evolution of the magnetopause standoff distance,  $R_s$ , at  $z = 0.2R_M$  obtained from Cases 2–4. The dashed lines with different colors indicate the points in time when the induced currents are well formed. The gray arrows in Case 4 indicate large FTEs formed at the dayside magnetopause.

line), when the induced currents at the core surface are well formed. Then, the magnetopause standoff distance gradually increases to  $1.43R_M$  at  $t = 29$  s. The peaks of the magnetopause standoff distance, indicated by the gray arrows, represent large-scale FTEs at the magnetopause. These large FTEs have a scale size of about  $0.3\text{--}0.5R_M$  in agreement with MESSENGER in situ measurement of the larger FTEs (Slavin, Lepping, et al., 2010). After the formation of a large FTE, the magnetopause standoff distance significantly decreases, indicating that the large-scale FTEs have a pronounced effect on the erosion of the planetary dayside magnetosphere. At about  $t = 100$  s, the magnetotail is well formed, and the magnetic flux returns to the dayside magnetosphere. The magnetopause standoff distance stabilizes at about  $1.15R_M$ .

Case 5, with a purely northward IMF, is performed to study the influence of the IMF direction while keeping other solar wind conditions the same as Case 3. The minimum magnetopause standoff distance of about  $1.11R_M$  occurs at  $t = 11$  s (indicated by the black dashed vertical line), which is the same as that in Case 3. Nevertheless, the magnetopause standoff distance stabilizes at about  $1.25R_M$  after  $t = 23$  s because of the absence of dayside magnetopause reconnection. Thus, it can be inferred that a strong solar wind dynamic pressure and a magnetopause reconnection significantly contribute to the disappearance of the dayside magnetosphere.

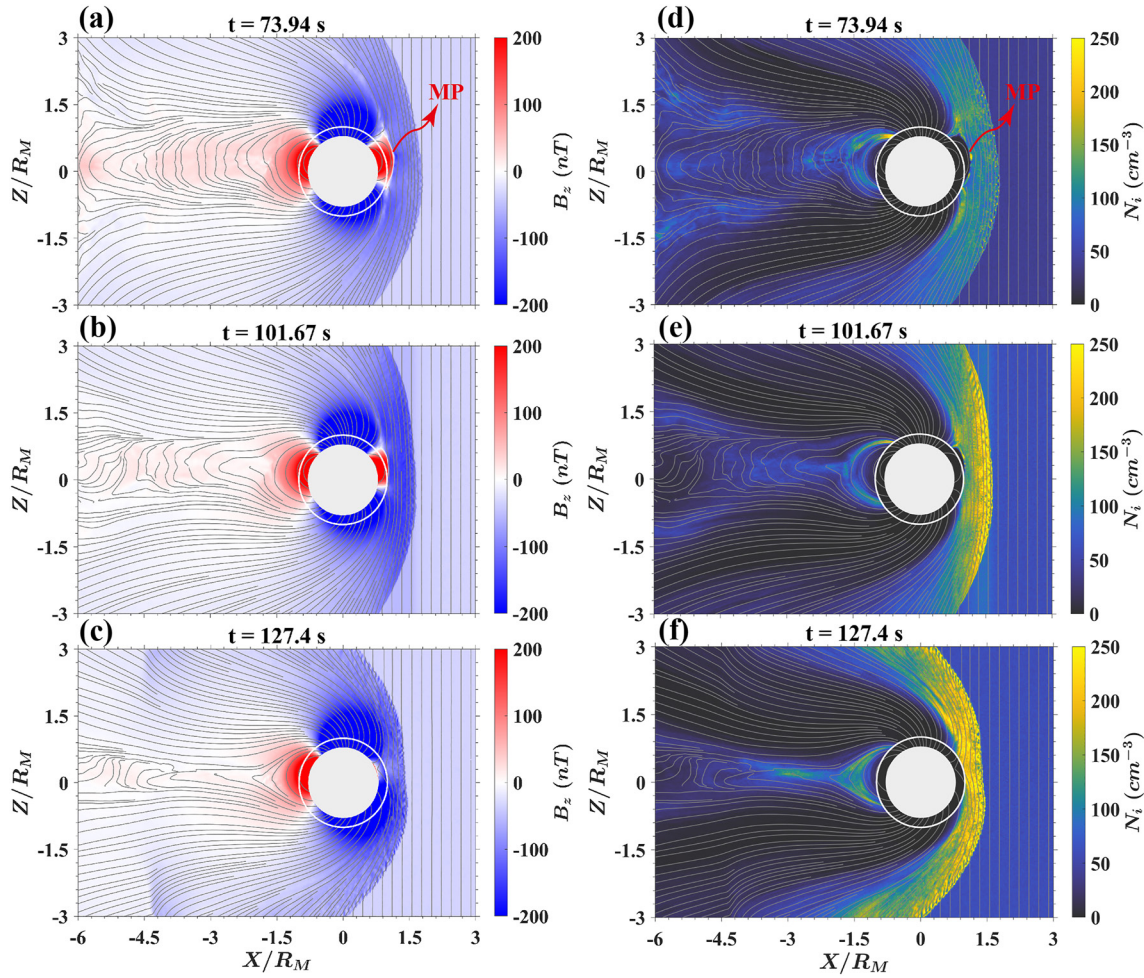

### 3.4. Effect of Return Flux on DDM Events

The return flux formed by the magnetotail reconnection or driven by the magnetopause reconnection is found to replenish the dayside magnetosphere (Juusola, Østgaard, & Tanskanen, 2011; Juusola, Østgaard, Tanskanen, Partamies, & Snekvik, 2011; Sun et al., 2017). In Cases 1–3, with dynamic pressure ranging from 25 to 107 nPa in the solar wind, the dayside magnetosphere disappears prior to the formation of the magnetotail. One issue is that if there is no magnetotail and the return flux at the beginning, it may be easy for the dayside magnetosphere to disappear. To address this issue, we perform another simulation with time-varying solar wind conditions (Case 6). Before  $t = 100$  s, the solar wind dynamic pressure is 8 nPa; to ensure the formation of the magnetotail, after  $t = 100$  s, the solar wind dynamic pressure increases to 25 nPa. Figure 8 shows the evolution of Mercury's magnetosphere in Case 6. At  $t = 73.94$  s (Figures 8a and 8d), the magnetotail begins to form, and the magnetopause stabilizes at about  $1.15R_M$  (at  $z = 0.2R_M$ ). When the solar wind with enhanced dynamic pressure impacts the dayside magnetosphere at  $t = 101.67$  s (Figures 8b and 8e), the dayside magnetosphere becomes significantly compressed. Finally, at  $t = 127.4$  s (Figures 8c and 8f), there are no closed magnetic field lines on the dayside hemisphere, which is consistent with the results of Case 3. From this case study (Case 6), it can be inferred that the return flux from the magnetotail under normal solar wind conditions cannot prevent the disappearance of the magnetosphere. Therefore, the solar wind dynamic pressure of Cases 1 and 2 is 107 and 56 nPa, respectively, and the return flux from the magnetotail under normal solar wind conditions is even more unable to prevent the disappearance of the dayside magnetosphere.

## 4. Discussion

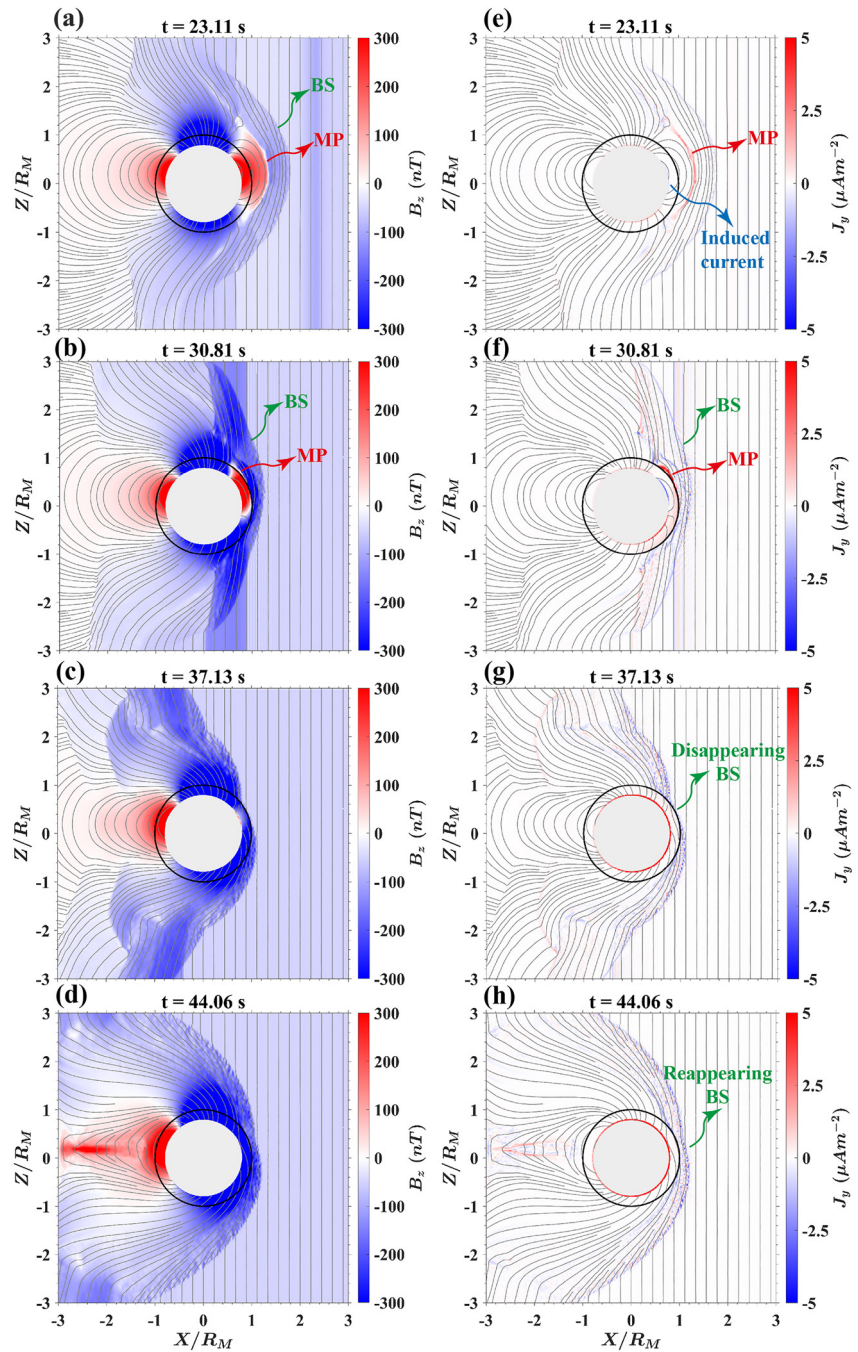

To avoid the influence of initialization on Case 1, we perform Case 7 with time-varying solar wind conditions. Before  $t = 23.11$  s (Figures 9a and 9e), the solar wind dynamic pressure is 8 nPa, and the magnetopause has been formed at  $t = 23.11$  s. Since the magnetopause is formed, the simulation is not initialized in a particular manner. After  $t = 23.11$  s, the solar wind dynamic pressure increased to 107 nPa. Due to the strong dynamic pressure in the solar wind, the dayside magnetosphere becomes highly compressed at  $t = 30.81$  s (Figures 9b and 9f). At  $t = 37.13$  s (Figures 9c and 9g), most of the dayside magnetosphere and the dayside bow shock disappear within 14 s after the arrival of the extreme solar wind. At  $t = 44.06$  s (Figures 9d and 9h), the dayside bow shock reappeared. The dayside bow shock disappears for about 7 s. These results are similar to those in Case 1 that initialized in a particular manner. Therefore, the influence of initialization on simulations is minimal.

Mercury is too small and hot for its gravity to retain a significant atmosphere. However, it does have a thin exosphere that is bound to the planetary surface. The atoms in the exosphere collide with the surface or escape from the planet, rather than colliding with each other. The first investigation of Mercury's exosphere came with the Mariner 10 flybys, where atomic hydrogen, helium, and oxygen were discovered using ultraviolet photometers (Broadfoot et al., 1976). Potter and Morgan (1985) later discovered strong emission features in the spectrum of Mercury at the Fraunhofer sodium (Na) D lines using ground-based telescopes and spectrometers. These emission features are attributed to the resonant scattering of sunlight from Na vapor in the planetary exosphere. The

total column abundance of Na was estimated to be  $8.1 \times 10^{11}$  atoms  $\text{cm}^{-2}$ . To understand the source processes of the Na exosphere of the planet, three mechanisms have been proposed: ion sputtering, photon-stimulated desorption (PSD), and meteoroid vaporization. Ion sputtering occurs when ions from the solar wind or Mercury's magnetosphere impact the planetary surface, resulting in the ejection of atomic Na with high velocity and energy (e.g., Ip, 1986; Killen et al., 1990; Killen & Morgan, 1993; Potter & Morgan, 1985, 1990, 1997). PSD occurs when solar photons hit the planetary surface and release their energy, breaking the bonds of surface materials and ejecting atomic Na from the surface (e.g., Cheng et al., 1987; McGrath et al., 1986; Peplowski et al., 2012; Wurz et al., 2010). Meteoroid vaporization occurs randomly, releasing high-energy atomic Na to high altitudes through collisions with the dust and some of the planetary surface (e.g., Cremonese et al., 2005; Morgan et al., 1988). McGrath et al. (1986) estimated that the average Na column abundance resulting from the ion sputtering is  $2 \times 10^7$ – $2 \times 10^8$   $\text{cm}^{-2}$ , assuming that a proton flux in cusp regions is  $10^8$ – $10^9$   $\text{cm}^{-2} \text{ s}^{-1}$ . However, this value cannot account for the observed Na column density. According to the method proposed by McGrath et al. (1986), the Na column abundance ( $N_{\text{col}}$ ) resulting from ion sputtering can be estimated as  $\Phi f \bar{Y} \tau$ . Here,  $\Phi$  is the ion flux at the dayside planetary surface,  $f$  is the fractional atomic concentration of Na in the surface layer,  $\bar{Y}$  is the surface-average yield, and  $\tau$  is the lifetime of an Na atom in the exosphere. Under the extreme solar wind condition shown in Case 1,  $\Phi$  can reach up to  $10^{10}$   $\text{cm}^{-2} \text{ s}^{-1}$  (see Figure 4a). Taking the values of  $f$ ,  $\bar{Y}$ , and  $\tau$  as 0.002, 0.1, and 1,000 s, respectively, the  $N_{\text{col}}$  resulting from ion sputtering is about  $2 \times 10^9$   $\text{cm}^{-2}$ . However, this estimated  $N_{\text{col}}$  during the DDM event is more than two orders of magnitude lower than the observed value of  $8.1 \times 10^{11}$   $\text{cm}^{-2}$ . Additionally, according to the method suggested by Sun et al. (2022), the exospheric surface

**Figure 9.** The evolution of the magnetopause and the bow shock in the noon-midnight meridian plane obtained from Case 7. (a–d) The magnetic field lines and the  $z$  component of magnetic field,  $B_z$ , at  $t = 18.49$  s, 30.81 s, 37.13 s, and 52.53 s. density of atomic Na ( $N_{\text{surf}}$ ) resulting from ion sputtering can be estimated as  $N_{\text{surf}} = \Phi f \bar{Y} / v_{\text{release}} = 7 \text{ cm}^{-3}$ , where  $v_{\text{release}}$  is considered to be  $3 \times 10^5 \text{ cm s}^{-1}$ . This estimated  $N_{\text{surf}}$  is also more than two orders of magnitude less than the observed value of  $10^3$ – $10^5 \text{ cm}^{-3}$  in the dayside hemisphere (Cassidy et al., 2015). Taking into account the maximum value of  $f$  to be 0.06 (Peplowski et al., 2014), the maximum  $N_{\text{surf}}$  is  $2 \times 10^2 \text{ cm}^{-3}$ , which is still less than the observed maximum  $N_{\text{surf}}$  of  $10^5 \text{ cm}^{-3}$  on the dayside hemisphere. The ion flux near the terminator can reach up to  $10^9 \text{ cm}^{-2} \text{ s}^{-1}$ , and the maximum  $N_{\text{surf}}$  near the terminator is  $20 \text{ cm}^{-3}$ . This value is also less than

the observed maximum  $N_{\text{surf}}$  of  $10^4 \text{ cm}^{-3}$  near the terminator (Cassidy et al., 2015). Therefore, ion sputtering may not be the primary source mechanism for the exospheric Na of Mercury even during the DDM events. The DDM events and its influence on the changes of Na in Mercury's exosphere will be further studied by the BepiColombo mission orbiting Mercury in 2025.

## 5. Conclusions

In this study, we investigate the DDM events at Mercury during extreme solar wind conditions using a 3-D global hybrid simulation model. When the dynamic pressure of the solar wind is 107 nPa and the magnitude of the purely southward IMF is 50 nT, most of the dayside magnetosphere disappears within 10 s of the interaction between the solar wind and planetary magnetic field. As a consequence, about 26% of the dayside surface of Mercury is in contact with the magnetosheath. The dayside bow shock mostly disappears at about  $t = 17.69$  s before the initiation of magnetotail reconnection. After the magnetotail reconnection is triggered, the magnetic flux returns to the dayside magnetosphere, and the dayside bow shock reappears at about  $t = 26.42$  s. Due to the disappearance of the dayside magnetosphere, the ion flux is significantly enhanced at most of the planetary dayside surface and reaches its maximum value of about  $10^{10} \text{ cm}^{-2} \text{ s}^{-1}$  at the low-latitude surface, which is much larger than that under normal solar wind conditions. However, it is still insufficient to explain the observed Na column abundance through ion sputtering.

The temporal evolution of magnetopause standoff distance under different solar wind conditions is also studied. When the solar wind dynamic pressure exceeds 25 nPa and the IMF is purely southward, part of the dayside magnetosphere disappears. The magnetopause standoff distance ( $z = 0.2R_M$ ) reaches  $1R_M$  at  $t = 27$  and 58 s when the solar wind dynamic pressure is 25 and 56 nPa, respectively. Under the same IMF, the higher the solar wind dynamic pressure, the faster the magnetopause standoff distance reaches the planetary surface. When the solar wind conditions are normal (with a dynamic pressure of 8 nPa and a purely southward IMF), the dayside magnetosphere does not disappear, and the magnetopause standoff distance stabilizes at  $1.15R_M$  after the magnetotail has been formed well at  $t = 100$  s. However, when the IMF is purely northward and the solar wind dynamic pressure is 25 nPa, the magnetopause standoff distance stabilizes at about  $1.25R_M$  after  $t = 23$  s due to the absence of dayside magnetopause reconnection.

## Data Availability Statement

In this study, the simulation data that are used to plot the figures can all be downloaded from Guo (2023).
